Topological origin of equatorial waves

Pierre Delplace, J. B. Marston, Antoine Venaille

TOPOLOGY

Topology sheds new light on the emergence of unidirectional edge waves in a variety of physical systems, from condensed matter to artificial lattices. Waves observed in geophysical flows are also robust to perturbations, which suggests a role for topology. We show a topological origin for two well-known equatorially trapped waves, the Kelvin and Yanai modes, owing to the breaking of time-reversal symmetry by Earth’s rotation. The nontrivial structure of the bulk Poincaré wave modes encoded through the first Chern number of value 2 guarantees the existence of these waves. This invariant demonstrates that ocean and atmospheric waves share fundamental properties with topological insulators and that topology plays an unexpected role in Earth’s climate system.

Symmetries and topology are central to an understanding of physics. In condensed matter, topology explains the precise quantization of the Hall effect (1), where a magnetic field breaks the discrete symmetry of time reversal. Interest in topological properties was reinvigorated after the discovery of the quantum spin Hall effect and the subsequent classification of different states of matter according to discrete symmetries (2). Recently, topologically protected edge excitations have been found in artificial lattices of various types (3–5). A correspondence between topological properties of waves in the bulk and the existence of unidirectional edge modes along boundaries exists in all these systems (6, 7). The edge modes fill frequency or energy gaps found in the bulk and are immune to various types of disorder. We show here that topologically protected edge waves also manifest in atmospheres and oceans.

Equatorial Kelvin and mixed Rossby-gravity (Yanai) waves are edge modes that propagate energy along Earth’s equator with eastward group velocity (8). Remarkably, the dispersion relations for these waves (Fig. 1A) were derived within the framework of the rotating-shallow-water model (9) just before their first observation in the 1960s. Since then, observations of the atmosphere have revealed a robust signature of these trapped modes in wave number–frequency spectra (10) (Fig. 1B). Equatorial Kelvin and Yanai waves have been shown to play a crucial role in several aspects of climate dynamics. For instance, Kelvin waves are a key component of the El Niño–Southern Oscillation, traveling across the waters of the Pacific Ocean (11). The waves are also part of the quasi-biennial oscillation in the stratosphere and are thought to be an important component of the Madden-Julian Oscillation in the troposphere (12).

The fact that Yanai and Kelvin waves are equatorially trapped unidirectional modes filling a frequency gap between the low-frequency planetary (Rossby) and high-frequency inertia-gravity (Poincaré) wave bands (6), as shown in Fig. 1A, suggests that they can be interpreted as topological boundary states, similar to those emerging in various topological insulating media. More precisely, bulk (Poincaré and/or Rossby) waves possess a topological property that should be directly related to the existence of these two unidirectional boundary waves by virtue of the bulk-boundary correspondence (6, 7).

to this correspondence, the number of states inherited by a band when the zonal (directed along the equator) wave number \( k_x \) varies from \(-\infty \) to \( +\infty \) is given by an integer-valued topological number called the first Chern number. The first Chern number quantifies the number of phase singularities in a bundle of eigenmodes parameterized on a closed manifold. These singularities are somewhat analogous to amphidromic points (\( \pm 2\pi \) phase vortices of tidal modes), but they occur in parameter space rather than in physical space. We demonstrate the existence of a nontrivial global structure in the bulk Poincaré modes as being encoded through the first Chern number of value \( \pm 2 \), thus ensuring the existence of two unidirectional edge modes at the equator that fill the two frequency gaps, in agreement with the existence of Kelvin and Yanai waves. The existence of the frequency gap originates from a broken time-reversal symmetry of the flow model owing to Earth’s rotation. The structure of tidal modes (13) and bifurcations in large-scale geophysical flow (14) have previously invoked the effect of breaking time-reversal symmetry. Our study shows that another far-reaching consequence of this broken symmetry is to confer nontrivial topological properties to bundles of fluid waves, giving rise to robust edge states. The rotating-shallow-water equations (8) that describe the dynamics of a thin layer of fluid on a two-dimensional surface of height \( h(x, t) \) and horizontal velocity \( \mathbf{u}(x, t) \) (where \( x \) is the horizontal coordinate and \( t \) is time) furnish a minimal model for equatorial waves

\[ \partial_t h + \nabla \cdot (\mathbf{u} h) = 0 \]

(1)

\[ \partial_t \mathbf{u} + (\mathbf{u} \cdot \nabla) \mathbf{u} = -g \nabla h - f \mathbf{n} \times \mathbf{u} \]

(2)

The Coriolis parameter \( f = 2 \Omega \times \mathbf{n} \) is twice the projection of the planetary angular rotation vector \( \Omega \) on the local vertical unit vector \( \mathbf{n} \) and \( g \) is the constant of gravitational acceleration. When linearized about a state of rest (\( \mathbf{u} = 0 \) and mean height \( h = H \)), this dynamical system may be rewritten as \( \partial_t \Psi = \nabla \Psi \), where \( \Psi = (\mathbf{u}, \eta) \) is a triplet of fields describing the two components of the perturbed velocity field and the perturbed height field \( \eta \), and where \( \mathcal{H} \) is a Hermitian operator (15). Because the fields \( \mathbf{u}, \eta \) are real, the operator \( \mathcal{H} \) is equal to the negative of its complex conjugate, \( \mathcal{H} = -\mathcal{H}^\dagger \). In the quantum context, the operation is referred to as a particle-hole transformation because it inverts the spectrum. Time-reversal symmetry \( T \rightarrow -T, x \rightarrow -x, \eta \rightarrow \eta, \mathbf{u} \rightarrow -\mathbf{u} \) is broken by a nonzero Coriolis parameter \( f \neq 0 \) in Eq. 2. The broken symmetry generates gaps in the shallow-water spectrum (8).

The \( f \)-plane approximation commonly used in geophysics (8) amounts to the neglect of Earth sphericity by assuming that the dynamics take place on a tangent plane with constant \( f \) (Fig. 2A). Translational symmetry ensures that eigenmodes of the linearized dynamics in this geometry are of the form \( \Psi = \varepsilon \exp(ik_x x - \omega t) \), where \( \Psi \) has three components. Viewing \( f/c \) as an external parameter, where \( c = \sqrt{gH} \) is the speed of gravity waves in nonrotating shallow water, the eigenmodes may be easily found at each point in the space \((k_x, k_y, f/c)\) (Fig. 2B). There are three bands with frequencies \( \omega_+ = \pm (f^2 + c^2k^2)^{1/2} \) and \( \omega_0 = 0 \), where \( k^2 = k_x^2 + k_y^2 \), with corresponding wave functions \( \{\Psi_+, \Psi_0, \Psi_-\} \). For \( f = 0 \), the bands are separated by gaps of frequency \( f \) (Fig. 3). The zero-frequency modes are in geostrophic balance; the other two modes are Poincaré waves with dispersions \( \omega_\pm \) that are symmetric with respect to the origin in \((k_x, k_y, f/c)\) space. Eigenmodes depend on the triplet of parameters \((k_x, k_y, f/c)\) that correspond to the set of waves in all possible \( f \)-plane configurations. The eigenmodes do not vary with the distance from the origin in \((k_x, k_y, f/c)\) space and can therefore be parameterized on the surface of a sphere \( S \) that encloses the singular band-crossing point at the origin \((k_x, k_y, f/c) = (0, 0, 0)\) (Fig. 2B and (15)). Each of the eigenstates \( \{\Psi_+, \Psi_0, \Psi_-\} \) defines a fiber bundle over \( S \) that may possess topological defects. The singularities reflect the impossibility of continuously defining the eigenmodes everywhere on the sphere, particularly over both of Earth’s two hemispheres simultaneously. They are quantified by the first Chern number \( \Delta \), which can be calculated for each bulk mode \( n \) as the flux of the Berry curvature \( W_n = -\nabla \times (\nabla \psi^* \nabla \psi, \nabla \psi) \) through the sphere \( S \), where \( W_n = i \nabla \psi^* \nabla \psi \) is the conjugate transpose of \( \psi_n \) and \( \nabla_\mathcal{H} = (\partial_\mathcal{H} \partial_{\mathcal{H}}^\dagger \partial_{\mathcal{H}}^\dagger \partial_{\mathcal{H}}^\dagger) \). In other words, there exists a quantized Berry flux generated by (a Berry) monopole located at the center of \( S \), where the three bands cross (16, 17). The singularities are analogous to the one exhibited by an electron wave function that cannot be continuously defined around a Dirac magnetic monopole (18). We find \( \Delta_- = \Delta_0 = \Delta_+ = \pm 2 \) (15); that is, only the Poincaré modes \( \Psi_\pm \) are topologically nontrivial because the geostrophic modes \( \Psi_0 \) have zero Chern index, in agreement with the bulk-boundary correspondence (6, 7).

To understand qualitatively the correspondence between these bulk properties and the emergence of unidirectional edge states in the presence of an equator, it is worth considering the case of a planar flow in an unbounded domain with \( f \) varying in the \( y \) direction from \(-2\Omega \) to \( 2\Omega \) (Fig. 3). Far from the interface, the eigenmodes are given by deformed solutions — i.e., by those computed in the case of constant \( f \). If one could continuously deform the whole set of positive-frequency eigenmodes from one hemisphere to other—for instance, by varying \( f \) slowly with \( y \)—then the eigenmodes would be given by solutions close to those calculated for constant \( f \). Our previous calculation shows that this continuous deformation is prohibited by the occurrence of \( \Delta_\pm = \pm 2 \) phase singularities (positive vortices) when the plane \( f = 0 \) is crossed. To remove these two singularities, the positive- and negative-frequency bands must be connected to each other because the sum of their Chern numbers is zero. This connection happens through the emergence of two edge states that fill the frequency gaps. For any frequency that lies within the bulk gaps, the number of topological edge states is fixed by the set of Chern numbers \( \delta \). Because \( \Delta_- = \pm 2 \), there are two extra unidirectional edge modes in the frequency gaps (15).

It is instructive to examine the Berry curvature for the Poincaré modes. As shown in Fig. 3, the curvature is mainly concentrated around \( k = 0 \), where it reaches extremal values, and, importantly, changes sign with \( f \). It follows that its flux for each Poincaré mode \( C_n = 1 \pi \int_{S^n} \omega_n \mathbf{d}k_x \mathbf{d}k_y \mathbf{B} = \pm \text{sgn}(f) \) is an integer that only depends on the hemisphere. It is thus tempting to say that the Poincaré eigenmodes on the two hemispheres are topologically distinct by interpreting \( C_\pm \) as a Chern number as well, given that the difference \( C_+(f > 0) - C_-(f < 0) = \pm 2 \) coincides with the first Chern number \( \Delta_- \). This would be rigorously true if the two-dimensional manifold through which this Berry flux is computed at \( f = \) constant were closed—for instance, when the wave numbers \( (k_x, k_y) \) live on a Brillouin zone that reflects an underlying lattice. For continuous fluids, only \( \Delta_- \) is a well-defined topological
number, but this suffices to characterize the topological property of the bulk modes and, thus, the existence of the two equatorial unidirectional modes.

We stress one important point concerning the role of the spherical geometry of the planet in our approach. We remove this sphericity with the f-plane approximation, equivalent to holding the Coriolis parameter constant in space. However, through the construction of the sphere S in parameter space (kx, ky, f/c), we recover the effect of a varying Coriolis parameter on the shallow-water eigenmodes. In this way, sphericity works its way back into the problem. The detailed geometry of Earth is no longer needed with Cartan label D, which means that nontrivial topology guarantees the existence of equatorial Yanai and Kelvin waves. Even a misshapen sphere can also be equatorially trapped. However, this robustness against disorder can now be understood as a consequence of topology.

Fig. 3. Dispersion relation in unbounded f-plane geometry for the two signs of f. The color indicates the Berry curvature Bn = −∇p × (ΨnΔpΨn) for each wave band indexed by n ∈ (−, 0, +). The Berry curvature of the Poincaré bands is Bn = ±fc2(kx2 + cy2 + k2)/2. It is concentrated around k = 0, with extremal value ±c2/2. The curvature vanishes for the geostrophic band. When integrated over the whole plane (kx, ky), the Berry fluxes in the three bands give integers (−1, 0, 1) for f > 0 and (1, 0, −1) for f < 0, consistent with the triplet of Chern numbers {ΔC−, ΔC0, ΔC+} = {−2, 0, 2}. This shows that the set of delocalized bulk Poincaré modes cannot be continuously deformed from one hemisphere to another.

The shallow-water system exhibits particle-hole symmetry stemming from real-valued velocity and displacement fields. More generally, any linearized fluid flow model that can be written in terms of a Hermitian operator that breaks time-reversal symmetry belongs to the symmetry class with Cartan label D, which means that nontrivial topological properties may arise (22, 29). Other physical systems that may belong to class D are chiral p-wave superconductors (46, 24) and superfluid 3He-A (25). The linear operator of flow dynamics can be non-Hermitian in the presence of mean flows and dissipation, in which case other topological properties may appear (26). We expect that topology may ultimately shape the global structure of a number of astrophysical and geophysical wave spectra where similar gaps opened in the presence of symmetry-breaking fields are known to exist. For instance, Lamb waves are edge states that fill the gap between acoustic and gravity waves because gravity breaks another discrete symmetry, that of inversion. Hall magnetohydrodynamics is another possible setting for topological edge waves (27). It will also be interesting to study in more detail the resilience of topological waves against dissipation and non-linear wave-scattering processes.

Fluid waves with topological origins

Topological effects that arise from material boundaries are well known in solid-state physics and form the basis for topological insulators. Delplace et al. describe atmospheric and ocean waves that appear to have a similar topological origin (see the Perspective by Biello and Dimofte). The waves exist because of the symmetry-breaking nature of Earth's rotation, which allows certain fixed topological constraints on the system. These findings may be useful for understanding a wide variety of geophysical and astrophysical flows.
