confirmed the close functionality of VAL1 and PHD-PRC2. *val1 vin3* and *val1 vrn2* plants were very delayed in flowering (Fig. 4D; table S8; and fig. S10, A to D) after 12 and 18 weeks of cold, and *FLC* expression remained high (fig. S10, E and F). This synergistic interaction is best explained by VAL1-VAL2 redundancy, with both proteins functioning through PHD-PRC2.

We propose that VAL1 binds sequence-specifically, probably as a homodimer, but potentially as a heterodimer with VAL2, to the RY motifs in the *FLC* nuclear region (Fig. 4E). This recruits the ASAP complex and potentially PRC1, resulting in the shutdown of transcription and reduced histone acetylation. In turn, these activities allow PHD-PRC2 nucleation and long-term epigenetic silencing of the locus. We cannot exclude the possibility of effects of VAL1 and VAL2 on *FLC* expression that are independent of the binding to *FLC* intron 1. The association of HDA19 with the PHD proteins suggests that it has multiple roles in the process, potentially interacting with VAL1 through SAP18 (26) for transcriptional repression and with VIN3 (and VRN5) to facilitate +1 nucleosome stabilization (27). It will now be important to investigate which components confer the switchlike off-on property that has been proposed for the nucleation event (29).

**SYMBIOSIS**

**Basidiomycete yeasts in the cortex of ascomycete macrolichens**

Toby Spribille,1,2 Veera Tuovinen,3,4 Philipp Resl,1 Dan Vanderpool,1 Heimo Wolinski,5 M. Catherine Aime,6 Kevin Schneider,1 Edith Stabentheiner,1 Merje Toome-Heller,6 Göran Thor,4 Helmut Mayrhofer,1 Hanna Johannesson,3 John P. McCutcheon2,7

For over 140 years, lichens have been regarded as a symbiosis between a single fungus, usually an ascomycete, and a photosynthesizing partner. Other fungi have long been known to occur as occasional parasites or endophytes, but the one lichen–one fungus paradigm has seldom been questioned. Here we show that many common lichens are composed of the known ascomycete, the photosynthesizing partner, and, unexpectedly, specific basidiomycete yeasts. These yeasts are embedded in the cortex, and their abundance correlates with previously unexplained variations in phenotype. Basidiomycete lineages maintain close associations with specific lichen species over large geographical distances and have been found on six continents. The structurally important lichen cortex, long treated as a differentiated ascomycete cells, appears to consistently contain two unrelated fungi.

Most definitions of the lichen symbiosis emphasize its dual nature: the mutualism of a single fungus and single photosynthesizing symbiont, occasionally supplemented by a second photosynthesizing symbiont in modified structures (1–4). Together, these organisms form stratified, often leafy or shrubby body plans (thalli) that resemble none of the factors involved in forming two macrolichen thalli (5, 6). Notably, a critical structural feature of stratified lichens, the cortex, typically remains rudimentary in laboratory-generated symbioses (5). Recently, it has been suggested that microbial players, especially bacteria, may play a role in forming complete, functioning lichen thalli (7). However, although culturing and amplicon sequencing have revealed rich communities of microbes (7, 8), including other fungi (8–10), no new stably associated symbiotic partners have been found.

The recalcitrance of lichens to form thalli in vitro means that characterizing symbiont gene activity (e.g., through transcriptomics) requires an approach that works with natural thalli. We used metatranscriptomics to better understand the factors involved in forming two macrolichen symbioses, *Bryoria fremontii* and *B. tortuosa*. Two of these species have been distinguished for 90 years by the thallus-wide production of the toxic substance vulpinic acid in *B. tortuosa*, causing it to appear yellowish, in contrast to *B. fremontii*, which is dark brown (11). Recent phylogenetic analyses have failed to detect any fixed sequence differences between the two species in either the mycobiont (Ascomycota, Lecanoromycetes, *Bryoria*) or the photobiont (Viridiplantae, *Trebouxia simplex*) when considering four and two loci, respectively (12, 13). We hypothesized that differential gene expression might account for the
increased production of vulpinic acid in *B. tortuosa*.

We first selected 15 thalli (six from *B. fremontii* and nine from *B. tortuosa*, all free from visible parasitic infection) from sites across western Montana, USA, for mRNA transcriptome sequencing. An initial transcriptome-wide analysis of single-nucleotide polymorphisms (SNPs) for Ascomycota and Viridiplantae transcript subsets showed no correlation between genotype and phenotype in *B. fremontii* and *B. tortuosa*, confirming previous results (12, 13) (Fig. 1, A and B).

Next, we estimated transcript abundances by mapping raw reads back to a single, pooled metatranscriptome assembly and binning by taxon. Restricting our analyses to Ascomycota and Viridiplantae revealed little differential transcript abundance associated with phenotype (Fig. 1, C and E). Taken together, these analyses confirm previous conclusions that the two lichen species are nomenclatural synonyms (12) but still provide no explanation for the underlying phenotypes (which we shall continue to refer to by their species names for convenience). However, by expanding the taxonomic range to consider all Fungi, we found 506 contigs with significantly higher abundances in vulpinic acid–rich *B. tortuosa* thalli. A majority of these contigs were annotated as Basidiomycota (Fig. 1D). These data suggested that a previously unrecognized basidiomycete was present in thalli of both species but was more abundant whenever vulpinic acid was present in large amounts.

We next sought to determine whether this uncharacterized basidiomycete was specific to the studied *Bryoria* species or could be found in other lichens. From metatranscriptome contigs containing ribosomal RNA (rRNA) basidiomycete sequences, we designed specific primers for ribosomal DNA (rDNA; 18S, internal transcribed spacer (ITS), and D1D2 domains of 28S) to screen lichens growing physically adjacent to *Bryoria* in Montana forests. Each assayed lichen species carried a genetically distinct strain of the basidiomycete, indicating a high degree of specificity. Furthermore, we found that *Letharia vulpina*, a common lichen species growing in association with *B. tortuosa*, maintained basidiomycete genotypes that were distinct from those in *Bryoria*, not only in Montana but also in northern Europe (fig. S1). When assaying for the basidiomycete across the seven main radiations of macrolichens in the class Lecanoromycetes, we found related basidiomycete lineages associated with 52 lichen genera from six continents, including in 42 of 56 sampled genera of the family Parmeliaceae (fig. S2). As a whole, these data indicate that basidiomycete fungi are ubiquitous and global associates of the world’s most speciose radiation (14) of macrolichens.

To place the basidiomycete lineages in a phylogenetic context, we generated a 349-locus phylogenomic tree by using gene sequences inferred from our transcriptome data set and other available genomes (table S1). This analysis placed the basidiomycete as sister to *Cyphobasidium minutum* (class Cystobasidiomycetes, subphylum Pucciniomycotina) with high support (Fig. 2A). The only previously known lichen-associated members of Cystobasidiomycetes are two species of *Cyphobasidium*, which is hypothesized to cause galls on species of Parmeliaceae (15). When incorporated into a broader sample of published cystobasidiomycete rDNA sequence data (16–18), the majority of our lichen-derived sequences form a strongly supported monophyletic clade with *Cyphobasidium* (Fig. 2B). Using current classification criteria (18), the lichen-associated lineages would include numerous new family-level lineages, and we recognize this set of subclades as the new order Cyphobasidiales (19). Applying a relaxed molecular clock to our phylogenomic tree
Fig. 2. Placement of Cyphobasidiales members and their diversity within lichens. (A) Maximum likelihood phylogenomic tree based on 39 fungal proteomes and 349 single-copy orthologous loci. Dating based on a 58-locus subsample shows relative splits between Cyphobasidiales and Cystobasidiaceae and splits leading to the lecanoromycete genera Xanthoria, Cladonia, and Bryoria (colored bars indicate 95% confidence intervals; fungi occurring in lichens are shown in green). (B) Maximum likelihood rDNA phylogeny of the class Cystobasidiomycetes, with images of representative lichen species from which sequences were obtained in each clade; thick branches indicate bootstrap support >70%. Shaded triangles are scaled to the earliest branch splits of underlying sequence divergence in each clade. Full versions of the trees are shown in fig. S3.

(Fig. 2A) shows the Cystobasidiomycetes-Cyphobasidiales split occurring around the same time as the origin of three of the major groups of lecanoromycetes macrolichens in which Cyphobasidiales species occur, suggesting a long, shared evolutionary history. Two fossil calibrations place this split at around 200 million years before the present (figs. S4 and S5).

Our initial microscopic imaging failed to reveal any cells that we could assign to Basidiomycetes with certainty. Furthermore, attempts to culture the basidiomycete from fresh thalli were unsuccessful. We therefore developed protocols for fluorescent in situ hybridization (FISH) targeting specific aascomycete and cystobasidiomycete rRNA sequences. Cystobasidiomycete-specific FISH probes unambiguously hybridized round, ~3- to 4-μm-diameter cells embedded in the peripheral cortex of both B. fremontii and B. tortuosa (Fig. 3 and movie S1). Consistent with the transcript abundance data, these cells were more abundant in thalli of B. tortuosa (Fig. 3), where they were embedded in secondary metabolite residues (movie S1). Imaging of other lichen species likewise revealed cells of similar morphology in the peripheral cortex (fig. S6). Composite three-dimensional FISH images from B. capillaris show the cells occurring in a zone exterior to the lecanoromycete (Fig. 4 and movie S2) and embedded in polysaccharides (Fig. 4C), explaining why these cells are not observed in scanning electron microscopy (Fig. 4A). In some species, such as L. vulpina, the abundance of hybridized living cells was low, but selective removal of the polysaccharide layer through washing revealed high densities of collapsed, apparently dead cells within the cortex (fig. S7). These dead cells may explain the paucity of the FISH signal in some experiments. The mononucleate single cells (fig. S8C), evidence of budding, and absence of hyphae or clamp connections are consistent with an anaerobic or yeast state in Cystobasidiomycetes.

FISH imaging of Cyphobasidium galls on the lichen Hypogymnia physodes, obtained from Norway, confirmed the link to the sexual or teleomorphic stage (fig. S6), which appears to develop rarely (15). These data suggest that the gall-inducing form of Cyphobasidium completes its life cycle entirely within lichens.

It is remarkable that Cyphobasidium yeasts have evaded detection in lichens until now, despite decades of molecular and microscopic studies of the Parmeliaceae (20–22). It seems likely that the failure to detect Cyphobasidium in both Sanger and amplicon sequencing studies (8) is due to multitemplate polymerase chain reaction bias. The most widespread clade of Cyphobasidium possesses a 595-base pair group I intron inserted downstream of the primer binding site ITS1F, doubling the template length of ITS, a popular fungal barcode (23). This, combined with low background abundance, can push a template below detection thresholds (24). Also, we cannot rule out that Cyphobasidium yeasts have actually been sequenced and discarded as presumed contaminants.

The lichen cortex layer has long been considered to be key for structural stabilization of macrolichens, as well as for water and nutrient transfer into the thallus interior (6, 25). Most macrolichens possess a basic two-layer cortex scheme consisting of conglutinated internal hyphae and a thin, polysaccharide-rich peripheral layer (25). However, the internal cellular structure is not uniform across lichens (26), and the composition of extracellular polysaccharides is poorly known (27). In Bryoria, the layer in which Cyphobasidium yeasts occur has not been recognized as distinct from the cortex (26), although in other parmelioid lichens, a seemingly homologous layer has sometimes been referred to as the “epicortex” (20). The discovery of ubiquitous yeasts embedded in the cortex raises the prospect that more than one fungus may be involved in its construction, and it could explain why lichens synthesized in vitro from axenically grown ascomycete and algal cultures develop only rudimentary cortex layers (5).

In many lichens, the peripheral cortex layer in which Cyphobasidium yeasts are embedded is enriched with specific secondary metabolites (25), the production of which often does not correlate with the lecanoromycete phylogeny (28).
The assumption that these substances are exclusively synthesized by the lecanoromycete must now be considered untested. In B. tortuosa, differential transcript and cell abundance data, along with physical adjacency to crystalline residues, implicate *Cyphobasidium* in the production of vulpinic acid, either directly or by inducing its synthesis by the lecanoromycete. Confirming a link by using transcriptome or genome data is impossible until the enzymatic synthesis pathway of vulpinic acid is described. However, related pulvinic acid derivatives are synthesized by other members of Basidiomycota (29).

The assumption that stratified lichens are constructed by a single fungus with differentiated cell types is so central to the definition of the lichen symbiosis that it has been codified into cell types. The discovery of *Cyphobasidiales* yeasts in science.

Increased plasmid copy number is essential for *Yersinia* T3SS function and virulence

**He Wang,1,2 Kemal Avican,1,2 Anna Fahlgren,1 Saskia F. Erttmann,1,2 Aaron M. Nuss,3 Petra Dersch,3 Maria Fallman,1,2 Tomas Edgren,1,2+ Hans Wolf-Watz1,2,+,†**

Pathogenic bacteria have evolved numerous virulence mechanisms that are essential for establishing infections. The enterobacterium *Yersinia* uses a type III secretion system (T3SS) encoded by a 70-kilobase, low-copy, IncFI1-class virulence plasmid. We report a novel virulence strategy in *Y. pseudotuberculosis* in which this pathogen up-regulates the plasmid copy number during infection. We found that an increased dose of plasmid-encoded genes is indispensable for virulence and substantially elevates the expression and function of the T3SS. Remarkably, we observed direct, tight coupling between plasmid replication and T3SS function. This regulatory pathway provides a framework for further exploration of the environmental sensing mechanisms of pathogenic bacteria.

**Fig. 1.** *Y. pseudotuberculosis* differentially regulates virulence plasmid copy number in vitro. (A) Virulence plasmid copy numbers in DNA isolated from *Y. pseudotuberculosis* YpIII/pIBX grown for 3 hours under different conditions [white, 26°C; gray, 37°C under T3SS-inductive conditions (Ca2+); black, 37°C under T3SS-repressive conditions (Ca2+-free)] as determined by whole-genome sequencing (TruSeq). Copy number was calculated as the ratio of average depth of plasmid DNA coverage to chromosomal DNA coverage (N = 2). (B) Time course of plasmid copy number increase determined by qPCR. At time zero, *Y. pseudotuberculosis* cultures were shifted from 26°C to 37°C under T3SS-repressive (gray) and T3SS-inductive (black) conditions. Plasmid copy number is defined as the number of plasmid equivalents per chromosome (N = 6). (C) Plasmid copy number changes in YpII/pIB73 (∆*lcrF*) and YpII/pIB621 (∆*yopD*) determined by qPCR after 3 hours of growth under the same conditions as in (A) (N = 6). (D) qPCR results showing plasmid copy numbers in YpII/pIBX (wt) and a YpII/pIB621 (ΔyopD) overexpressing the antisense copA RNA fused to the yopE promoter in cis (pyoE-copA) after 3 hours of growth at 37°C under T3SS-repressive (gray) and T3SS-inductive (black) conditions. Copy numbers in YpII/pIBX (wt) are shown as control (N = 4). Inset: Immunoblot of whole-cell lysates from the indicated strains probed with antibodies to Yops. Data are means ± SEM (*P ≤ 0.05, **P ≤ 0.01, ***P ≤ 0.001, Mann-Whitney U test; ns, not significant).
Basidiomycete yeasts in the cortex of ascomycete macrolichens

Lichens assemble in three parts
Lichen growth forms cannot be recapitulated in the laboratory by culturing the plant and fungal partners together. Spribille et al. have discovered that the classical binary view of lichens is too simple. Instead, North American beard-like lichens are constituted of not two but three symbiotic partners: an ascomycetous fungus, a photosynthetic alga, and, unexpectedly, a basidiomycetous yeast. The yeast cells form the characteristic cortex of the lichen thallus and may be important for its shape. The yeasts are ubiquitous and essential partners for most lichens and not the result of lichens being colonized or parasitized by other organisms.
